1 Overview of the Wireless Manager

1.1 Role of the Wireless Manager

The *wireless manager* (WM) is situated between the wireless communication hardware and applications. It receives information and shares that information directly with the hardware. The wireless manager is a library providing relatively low-level parts.

The *wireless manager library* is mainly an implementation of a game-specific wireless communication method. The wireless manager library provides a unique protocol called the *MP communication protocol*. Frameworks are also included, such as a data sharing function that operates on that protocol.

This document explains the fundamentals needed to use the wireless manager. This document also includes explanations, taking sample programs as examples and implementing them in real applications.

1.2 MP Communication Protocol

As with the programming manual, there are three separate ways to use the DS wireless features depending on your purposes. The three modes are:

- Infrastructure
- DS Wireless Play
- Single-Card Play

This tutorial addresses only the DS Wireless Play mode.

In DS Wireless Play mode, communication occurs wirelessly while each connected device has a game card inserted. In Single-Card Play mode, a game card is inserted in one machine, and the other machines operate by downloading the program from that machine. In Infrastructure mode, communication occurs using the Internet.

When communicating wirelessly after a program downloaded in Single-Card Play mode has started, communication occurs in either the DS Wireless Play or Infrastructure mode.

The protocol normally used in DS Wireless Play mode is called the *MP (Multi Poll) Communication* protocol. This protocol provides the functionality called *sending and receiving data in real-time with multiple machines*, which is necessary in many communication game applications.

Using the MP communication protocol, communication occurs in the following steps as one cycle:

- 1. The parent delivers (broadcasts) data to all children.
- 2. All children return a response to the parent.
- 3. The parent notifies (broadcasts) that the communication cycle is finished.

© 2004-2006 Nintendo 5 NTR-06-0251-002-A2 CONFIDENTIAL Released: February 2, 2006

Note that each child communicates directly with only the parent and does not communicate directly with other children. Also, the real-time aspect is a priority. As such, another feature is that instead of being able to perform communication of one to several cycles in one picture frame (1/60th of a second), the amount of sendable/receivable data in one cycle is comparatively small.

1.3 Data Sharing

Data sharing is a communication method for realizing on the MP communication protocol a technique called *sharing data in real-time with all communicating devices*, used frequently by game applications. This technique is realized in such a way that the parent collects data from each child, lumps it together, and then delivers it to all children as *shared data*.

Pulling this together (as in the steps mentioned in section 1.2), the steps are:

- 1. The parent distributes shared data to all children.
- 2. Each child responds with its own specific information to the parent.
- 3. The parent collects returned information as shared data for the next send.

Note that the shared data received by each child is the data the parent collected from each child in the previous cycle.

Key sharing treats each device's key data as shared data.

Data sharing is one sample application of the MP communication protocol. Key sharing is one example of how to use data sharing. These three terms should not be spoken of on the same level but, depending on the circumstances, they may be described in parallel in the manual or sample programs. Do not confuse these terms. This manual primarily covers data sharing.

2 Operating the Wireless Manager

2.1 Organization of the Wireless Manager

In the Nintendo DS, the wireless communication unit is connected to the ARM7 bus (see the hardware block diagram in the "NITRO Programming Manual"). In other words, the wireless communication unit is under the control of the subprocessor (ARM7).

Therefore, to control the communication features from the *main processor* (ARM9) in a normal game, it is necessary to go through the *subprocessor* (ARM7). Many WM-related APIs have been implemented as asynchronous functions for streaming requests to the ARM7 in FIFO. Because the result of the request is also sent via FIFO, it is received by the main processor, causing the callback stored by the user to be invoked. This allows you to obtain the result.

In the sample programs covered in this tutorial, this *issue request and receive results with callback* operation is treated as one set. Serial processing is basically realized as follows (A and A', and B and B' are sets).

- 1. Call function A to send a request to ARM7. (Make the callback set at this time A'.)
- 2. Send notification that A' was called and processing is complete. A' calls function B to send the next request.
- 3. B' is called, which was set when calling B, and B' calls C.
- 4. (The same pattern repeats.)

2.2 Transitioning Between Internal States

The ARM7 that controls wireless communication is a machine that goes back and forth between several internal states. The following figure shows the main internal states.

STOP

IDLE

PARENT CHILD SCAN

MP_PARENT MP_CHILD

Figure 2-1 Transitions Between Wireless Communication Internal States

Only the states needed for this explanation appear in this diagram. There is a more detailed figure showing transitions between internal states in the "NITRO SDK Function Reference Manual."

Each of the transitions shown above with arrows has a corresponding function. You can advance the processing by calling them in order. With few exceptions, you can transition from a state only to a neighboring state connected by arrows. For example, you cannot transition in a single bound from IDLE to MP_CHILD.

3 Implementing the dataShare-Model

This completes the discussion of the fundamentals necessary for understanding the SDK sample program (dataShare-Model). Additional considerations of the sample program follow.

The sample program implements data sharing using the WH library wrapper libraries, wh.h, wh_config.h, and wh.c (hereafter referred to as the WH library). The functions needed to implement normal wireless communication programs are gathered in the WH library. (The sample source code for the WH library is stored below the \$NitrosDK/build/demos/wireless shared/wh directory.)

This section explains how to use the WH library for sample program tasks, such as:

- Initializing
- Connecting
- Processing Synchronously
- Disconnecting and Terminating Processing

3.1 Initializing

This section describes the procedure to implement data sharing using the WH library.

The various wireless settings listed in $wh_config.h$ should be adjusted to match the specifications of the application. Wireless communication establishes virtual communication channels called "ports," and if the application uses MP communication in addition to data sharing, the port numbers for each must not conflict.

The maximum send/receive size for data sharing is limited by the number of children connected. To use data sharing for large volumes of data, these values must be adjusted accordingly.

The DMA channels used by the WM library are also set here. Change the values so that there is no conflict with the DMA channels used by the application for other processes, such as the FS library and GX library.

```
// DMA number used by wireless
#define WH DMA NO
// Max. number of children (Not including parents)
#define WH CHILD MAX
// Max. size of shareable data
#define WH DS DATA SIZE
                           12
// Max size of data that can be sent in one communication
// If using normal communication in addition to data sharing, increase
// this value as needed. Be sure to add the size of the additional
// headers/footers resulting from sending multiple packets.
// For details, see docs/TechnicalNotes/WirelessManager.doc.
// GUIDELINE: Guideline Standard Points (6.3.2)
// We recommend the keeping the time required for a single MP communication
// as calculated by the reference's wireless manager (WM)→Tables/information→
// wireless communication time calculation sheet
// under 5,600 microseconds.
// Port used for normal MP communication
#define WH DATA PORT 14
// Priority used for normal MP communication
#define WH DATA PRIO WM PRIORITY NORMAL
// Port used for data sharing
#define WH DS PORT
```

Next, define the type of data to share. When the maximum number of connected children is 15, a maximum of 12 bytes can be shared using data sharing. (The sharable data size varies with the maximum number of connected children.) The data size must not exceed 12 bytes.

```
typedef struct ShareData_ {
   u8 macadr[4]; // MAC address
   u32 count; // frame count
   u16 level; // signal reception strength
   s16 data; // graph display information
}ShareData;
```

Next, confirm the shared data region for send/receive in the program. For the receive buffer, the region (in bytes) must be at least (shared data size x (maximum number of connected children + 1)).

```
static u8 sSendBuf[256] ATTRIBUTE_ALIGN(32);
static u8 sRecvBuf[256] ATTRIBUTE ALIGN(32);
```

Next, set the V-Blank interrupt. The V-Blank interrupt is needed in section "3.3 Processing Synchronously."

```
// interrupt setting
OS_SetIrqFunction( OS_IE_V_BLANK , VBlankIntr );
(void)OS_EnableIrqMask( OS_IE_V_BLANK );
(void)GX_VBlankIntr( TRUE );
(void)OS_EnableIrq();
(void)OS_EnableInterrupts();
```

The necessary preparations in the program are completed, so use <code>WH_Initialize</code> to initialize wireless communications.

The $WH_Initialize$ function allocates the send/receive data buffer necessary for wireless communication and performs all processing necessary to initialize the wireless hardware. We recommend using the $WH_Initialize$ function unless you want to perform detailed settings in the program.

3.2 Connecting

In the sample program, the process enters the main loop after the $WH_Initialize$ function ends and then branches by referencing the wireless communications state returned by the $WH_GetSystemState$ function and the state variable sSysMode, which is changed using a menu selection.

.

This is the relevant portion of the sample program:

```
switch (whstate)
case WH SYSSTATE ERROR:
   // WH state has priority when error occurs
   changeSysMode(SYSMODE ERROR);
   break;
case WH SYSSTATE MEASURECHANNEL:
      u16 channel = WH GetMeasureChannel();
      sTgid++;
      (void) WH ParentConnect (WH CONNECTMODE DS PARENT, sTgid, channel);
   break;
default:
  break;
PR ClearScreen (&sInfoScreen);
// Load test.
forceSpinWait();
switch (sSysMode)
case SYSMODE SELECT ROLE:
   // Role (Parent & Child) selection screen
   ModeSelectRole();
   break;
case SYSMODE SELECT CHANNEL:
   // Channel selection screen.
   ModeSelectChannel();
   break;
case SYSMODE LOBBY:
   // Lobby screen.
   ModeLobby();
   break;
```

If initialization is successful, the state becomes <code>WH_SYSSTATE_IDLE</code> (the idle state) immediately after the <code>WH_Initialize</code> function ends. The initial value of <code>sSysMode</code> is <code>SYSMODE_SELECT_ROLE</code>.

The first routine to get called is <code>ModeSelectRole</code>. If Start (Parent mode) has been selected in <code>ModeSelectRole</code>, the parent-mode connection process is performed. If Start (Child mode) has been selected, the child-mode connection process is performed.

3.2.1 Connecting in Parent Mode

The parent must select a channel to use before communications can begin. In the sample program, the channel is decided in one of two ways: manual selection and automatic selection.

Manual selection is performed by the <code>ModeSelectChannel</code> routine, which is called when <code>Select channel</code> is chosen from the menu screen. The <code>WH_GetAllowedChannel</code> function is used to get a list of usable communications channels from which to the selection can be made.

For automatic selection, the WH_StartMeasureChannel function is first used to measure the radio-wave usage condition, and after this is completed the WH_GetMeasureChannel function is called to get the most open channel. You can determine whether the WH_StartMeasureChannel function has completed measurement of radio wave usage by checking whether it has returned WH SYSSTATE MEASURECHANNEL.

After that, to start connection of data sharing in parent mode, the WH_ParentConnect function gets called with the first argument set to WH_CONNECTMODE_DS_PARENT and the third argument set to the selected channel.

3.2.2 Connecting in Child Mode

To begin a connection in the child mode of data sharing requires first scanning to find parents and then deciding which parent to make a connection with.

In the sample program, the ModeSelectRole routine begins scanning for parents by calling the WH StartScan function.

The callback specified in the first argument of the WH_StartScan function gets called each time a parent is discovered during scanning. The scanCallback routine actually specified for this argument in the sample program performs a process that registers discovered parents in a list. A bitmap of valid channels is specified for the third argument, but it is not necessary to check ahead of time whether the specified channels are valid.

The ModeSelectParent routine, which is called during scanning, displays the parents found by scanning, and waits for the user to select one.

To start the connection in the child mode of data sharing, first end the scan with the WH_EndScan function and check that the WH_GetSystemState function returns WH_SYSSTATE_IDLE, and set WH_CONNECTMODE_DS_CHILD to the first argument and call the WH_ChildConnect function.

3.3 Processing Synchronously

When the connection completes normally in the parent or child mode of data sharing, the state obtained with the WH_GetSysState function transitions to WH_SYSSTATE_DATASHARING (data sharing).

For stable wireless communication, you must call the synchronous processing function <code>WH_StepDS</code> before starting the MP communication cycle of that frame. For the V-count where the WM library prepares MP communication, the parent is 260 and the child is 240 by default. It is designed to be as efficient as possible when called with the V-Blank interrupt (V-count is 192). With this in mind, the sample program calls the <code>WH_StepDS</code> function inside the <code>updateShareData</code> routine immediately after the start of the V-Blank interrupt (i.e., immediately after the <code>OS WaitVBlankIntr</code> function).

```
static void updateShareData(void)
   if (WH GetSystemState() == WH SYSSTATE DATASHARING)
      if (WH StepDS(sSendBuf))
          u16 i;
          for (i = 0; i < WM NUM MAX CHILD + 1; ++i)
             u8 *adr;
             ShareData *sd;
             adr = (u8 *)WH GetSharedDataAdr(i);
             sd = (ShareData *) & (sRecvBuf[i * sizeof(ShareData)]);
             if (adr != NULL)
                MI_CpuCopy8(adr, sd, sizeof(ShareData));
                sRecvFlag[i] = TRUE;
             }
             else
                sd->level = 0;
                sd->data = 0;
                sRecvFlag[i] = FALSE;
          sNeedWait = FALSE;
      }
      else
          for (i = 0; i < WM NUM MAX CHILD + 1; ++i)
             sRecvFlag[i] = FALSE;
         sNeedWait = TRUE;
      }
   else
      u16 i;
      for (i = 0; i < WM NUM MAX CHILD + 1; ++i)
          sRecvFlag[i] = FALSE;
      sNeedWait = FALSE;
```

For data shared by synchronous processing, obtain the top address using the WH GetSharedDataAdr function and copy it to the receive data region allocated in the program.

In the main loop, use the WH GetConnectMode function to determine the connection mode. If in the

parent mode, call the ModeParent routine. If in the child mode, call the ModeChild routine. The send/receive results are displayed in each routine.

The link strength icon is also displayed, which graphically shows the strength of the communication link while sharing data.

3.4 Disconnecting and Terminating Processing

When you want to disconnect a specific child from its parent with a user operation, use the WM_Disconnect function. When you want to disconnect multiple or all children at once, use the WM_DisconnectChildren function.

Using the WH library, when you want to terminate wireless communication by calling the <code>WH_Finalize</code> function, you can perform the appropriate end processing by evaluating the connection mode and the current WH library state. With the <code>WH_Finalize</code> function, wireless communication transitions to the IDLE state. From there, by sequentially calling the <code>WM_PowerOff</code>, <code>WM_Disable</code>, and <code>WM_Finish</code> functions (or the <code>WM_End</code> function to perform all three), you can completely finish, including disconnecting the wireless communication hardware.

4 WH Library

The WH library is a collection of functions needed to implement normal wireless communication programs. This section explains the functions collected in the WH library (including functions not used in the sample programs).

4.1 Function Reference (Initialization, Termination, Reset)

This section discusses the functions that initialize, terminate, and reset

4.1.1 WH_Initialize Function

C Specification: int WH_Initialize(void);

Arguments: None

Return Values: TRUE Success

FALSE Failure

Normally, $WH_Initialize$ automatically allocates the communication send/receive data buffer necessary for wireless communication and initializes wireless communication hardware. The wireless communication state transitions to IDLE. When TRUE is returned, the WM_Init function succeeded, and the WM_Enable function was called successfully. Initialization processing is complete when the return value of the WH GetSystemState function becomes WH SYSSTATE IDLE.

You must create a heap in the main memory for the internally-called OS Alloc function.

4.1.2 WH_Finalize Function

C Specification: int WH_Finalize(void);

Arguments: None

Return Values: TRUE Success

FALSE Failure

WH_Finalize calls the appropriate end process determined from the WH library state and the connection mode. The wireless communication state transitions to IDLE after processing completes. When TRUE is returned, the function call for end processing succeeded. The processing ends when the return value of the WH GetSystemState function becomes WH SYSSTATE IDLE.

To completely terminate wireless communication, you must call the WM_PowerOff, WM_Disable, and WM Finish functions, or just the WM End function.

4.1.3 WH Reset Function

```
C Specification:
                      int WH Reset (void);
Arguments:
                      None
Return Values:
                              TRUE
                                      Success
                      FALSE
                              Failure
```

WH Reset transitions the wireless communication state to IDLE regardless of the current state (such as connection mode). When TRUE is returned, the WH Reset call succeeded. The process completes when the return value of WH GetSystemState becomes WH SYSSTATE IDLE.

4.2 Function Reference (Connection)

This section discusses the two connection functions, WH ForceChannel and WH Connect.

4.2.1 WH ParentConnect Function

```
C Specification:
                       BOOL WH ParentConnect(int mode, u16 tgid, u16 channel);
Arguments:
                       mode
                                      Connection mode
                       tgid
                                       Parent communication tgid
                       channel
                                       Parent communication channel
Return Values:
                       TRUE
                                       Success
                                        Failure
                       FALSE
Connection mode definitions:
enum {
   WH CONNECTMODE MP PARENT, // Parent MP connection mode
   WH_CONNECTMODE_MP_CHILD, // Child MP connection mode
WH_CONNECTMODE_KS_PARENT, // Parent key-sharing connection mode
   \verb|WH_CONNECTMODE_KS_CHILD|, // Child key-sharing connection mode|\\
   WH CONNECTMODE DS PARENT, // Parent data-sharing connection mode
   WH CONNECTMODE DS CHILD, // Child data-sharing connection mode
   WH CONNECTMODE NUM
};
```

This function starts the wireless communication connection in parent mode. It automatically transitions to data sharing and key sharing. When TRUE is returned, the function call for connection processing succeeded. Whether for a parent or child, the process completes when the WH GetSystemState function returns the following return values: MP connection is WH SYSSTATE CONNECTED, data sharing is wh sysstate datasharing, and key sharing is wh sysstate keysharing.

4.2.2 WH_ChildConnect Function

```
C Specification:
                       BOOL WH ChildConnect(int mode, WMBssDesc *bssDesc);
Arguments:
                      bssDesc
                       mode
                                      Connection mode
                                     bssDesc of parent connecting to
Return Values:
                          TRUE
                                               Success
                       FALSE
                                 Failure
Conneciton mode definitions:
enum {
   WH CONNECTMODE MP PARENT, // Parent MP connection mode
   WH CONNECTMODE MP CHILD, // Child MP connection mode WH_CONNECTMODE_KS_PARENT, // Parent key-sharing connection mode
   WH CONNECTMODE KS CHILD, \,\, // Child key-sharing connection mode
   WH CONNECTMODE DS PARENT, \ //\ Parent data-sharing connection mode
   WH CONNECTMODE DS CHILD, // Child data-sharing connection mode
   WH CONNECTMODE NUM
};
```

This function starts the wireless communication connection in child mode.

4.3 Function Reference (MP Communication)

4.3.1 WH_SetReceiver Function

```
C Specification: void WH_SetReceiver(WHReceiver proc);
Arguments: proc WHReceiver type callback function
Return Values: None

WHReceiver type definitions:
    typedef void (*WHReceiver)(u16 aid, u16* data, u16 size);
```

WH_SetReceiver sets the MP communication data receive callback function. There is no need to set this when data sharing or key sharing.

The send source aid, received data, and receive data size are passed to the callback function.

4.3.2 WH_SendData Function

WH_SendData starts an MP communication data send. You do not need to call this when data sharing or key sharing. When TRUE is returned, the WM_SetMPDataToPortEx function call succeeded. The process completes when the callback function is called.

The send results are passed to the callback function. You must not change the contents of the send data buffer until the callback function is called.

4.4 Function Reference (Data Sharing)

4.4.1 WH_StepDS Function

C Specification: int WH_StepDS(void *data);
Arguments: data top address of send data

Return Values: TRUE Success

FALSE Failure

WH_StepDS proceeds to the next step in the synchronous processes for data sharing. When TRUE is returned, the process is complete. To get shared data, use the WH GetSharedDataAdr function.

For stable wireless communication, you must call this function before starting the MP communication cycle of that frame. We recommend calling it immediately after starting the V-Blank interrupt.

4.4.2 WH_GetSharedDataAdr Function

C Specification: u16 *WH GetSharedDataAdr(u16 aid);

Arguments aid aid of child you want to get shared data for Return Values: top address of shared data of specified child

NULL is returned when it fails.

Call WH GetSharedDataAdr when you want to get data sharing shared data by specifying the child.

4.5 Function Reference: Key Sharing

4.5.1 WH_GetKeySet Function

C Specification: int WH_GetKeySet(WMKeySet *keyset);

Arguments: keyset pointer to buffer that stores shared key data

Return Values: TRUE Success

FALSE Failure

WH_GetKeySet stores key data shared with key sharing in the buffer. The process is complete when TRUE is returned.

For stable wireless communication, the <code>WH_GetKeySet</code> function must be called before starting MP communication cycle of that frame. We recommend calling immediately after starting the V-Blank interrupt.

4.6 Function Reference: Get State

4.6.1 WH_GetAllowedChannel Function

```
C Specification: u16 WH_GetAllowedChannel(void);
```

Arguments: None

Return Values: bit pattern of communication channels permitted for use

Internally, WH GetAllowedChannel calls the WM GetAllowedChannel function.

4.6.2 WH GetConnectMode Function

```
C Specification: int WH_GetConnectMode(void);
```

Arguments: None

Return Values: the set connection mode

WH_GetConnectMode returns the connection mode set as an argument with the WH_ChildConnect function. The return values are undetermined until WH_ChildConnect is called. Until the next time WH ChildConnect is called, the previously-set connection mode is returned.

4.6.3 WH_GetBitmap Function

```
C Specification: u16 WH_GetBitmap(void);
Arguments: None
Return Values: bit pattern showing connected terminal
```

The bit corresponding to the connected terminal is set to 1. The lowest bit corresponds to the parent (aid=0), and the highest bit corresponds to the 15th child (aid=15).

4.6.4 WH_GetSystemState Function

```
C Specification:
                     int WH GetSystemState(void);
Arguments:
                     None
Return Values:
                            Internal state of WH library
Definitions of WH library internal states:
   WH SYSSTATE STOP,
                          // initial state
                         // standing by
   WH SYSSTATE IDLE,
   WH_SYSSTATE_SCANNING, // scanning
   WH SYSSTATE BUSY,
                          // connecting
   WH SYSSTATE CONNECTED, // connection complete (communication is possible in
this state)
   WH SYSSTATE DATASHARING, // connected with data-sharing enabled
   WH_SYSSTATE_KEYSHARING, // connected with key-sharing enabled
                          // error has occurred
   WH SYSSTATE ERROR,
   WH SYSSTATE NUM
};
```

WH GetSystemState obtains the current internal state of the WH library.

4.6.5 WH_GetLastError Function

```
C Specification: int WH_GetLastError(void);
Arguments: None
Return Values: error code

Definitions of error codes: enum {
    // your own error codes
    WH_ERRCODE_DISCONNECTED = WM_ERRCODE_MAX, // disconnected from parent
    WH_ERRCODE_PARENT_NOT_FOUND, // no parent
    WH_ERRCODE_NO_RADIO, // wireless use not possible
    WH_ERRCODE_LOST_PARENT, // parent not found
    WH_ERRCODE_MAX
};
```

 $\mathtt{WH_GetLastError} \ \textbf{obtains} \ \textbf{the details of the error that just occurred}.$

5 Appendix

5.1 WH_StateInXXXX and WH_StateOutXXXX Functions

As stated in "2.1 Organization of the Wireless Manager," the Wireless Manager API performs wireless communication with a combination of the request send function (call function) and the callback function that receives notification.

For internal functions in the WH library, the request send function is $WH_StateInXXXX$ and the callback function is $WH_StateOutXXXX$.

5.1.1 Parent/Child Shared Functions in WH and WM

Table 5-1 Corresponding WM Functions (Parent/Child Shared Functions)

| WH Library Function Names | Corresponding Wireless Manager Function |
|---------------------------|---|
| WH_StateInInitialize | WM_Init |
| WH_StateInEnable | WM_Enable |
| WH_StateOutEnable | |
| WH_StateInPowerOn | WM_PowerOn |
| WH_StateOutPowerOn | |
| WH_StateInReset | WM_Reset |
| WH_StateOutReset | |
| WH_StateInSetMPData | WM_SetMPDataToPortEx |
| WH_StateOutSetMPData | |
| WH_StateInPowerOff | WM_PowerOff |
| WH_StateOutPowerOff | |
| WH_StateInDisable | WM_Disable |
| WH_StateOutDisable | |

5.1.2 Parent Functions in WH and WM

Table 5-2 Corresponding WM Functions (Parent Functions)

| WH Library Function Names | Corresponding Wireless Manager Function |
|--------------------------------|---|
| WH_StateInMeasureChannel | WM_GetAllowedChannel |
| WH_NextMeasureChannel | WM_MeasureChannel |
| WH_StateOutMeasureChannel | |
| WH_StateInSetParentParam | WM_SetParentParameter |
| WH_StateOutSetParentParam | |
| WH_StateInStartParent | WM_StartParent |
| WH_StateOutStartParent | |
| WH_StateInStartParentMP | WM_StartMP |
| WH_StateOutStartParentMP | WM_StartDataSharing is also called when in data sharing mode. |
| WH_StateInStartParentKeyShare | WM_StartKeySharing |
| WH_StateOutStartParentKeyShare | |
| WH_StateInEndParentKeyShare | WM_EndKeySharing |
| WH_StateOutEndParentKeyShare | |
| WH_StateInEndParentMP | WM_EndMP |
| WH_StateOutEndParentMP | |
| WH_StateInEndParent | WM_EndParent |
| WH_StateOutEndParent | |
| WH_StateInDisconnectChildren | WM_DisconnectChildren |
| WH_StateOutDisconnectChildren | |

5.1.3 Child Functions in WH and WM

Table 5-3 Corresponding WM Functions (Child Functions)

| WH Library Function Names | Corresponding Wireless Manager Function |
|-------------------------------|---|
| WH_StateInStartScan | WM_GetAllowedChannel |
| WH_NextScan | WM_StartScan |
| WH_StateOutStartScan | |
| WH_StateInEndScan | WM_EndScan |
| WH_StateOutEndScan | |
| WH_StateInStartChild | WM_StartConnect |
| WH_StateOutStartChild | |
| WH_StateInStartChildMP | WM_StartMP |
| WH_StateOutStartChildMP | WM_StartDataSharing is also called when in data sharing mode. |
| WH_StateInStartChildKeyShare | WM_StartKeySharing |
| WH_StateOutStartChildKeyShare | |
| WH_StateInEndChildKeyShare | WM_EndKeySharing |
| WH_StateOutEndChildKeyShare | |
| WH_StateInEndChildMP | WM_EndMP |
| WH_StateOutEndChildMP | |
| WH_StateInEndChild | WM_Disconnect |
| WH_StateOutEndChild | |
